(Received January 26, 1987)

Energy and particle confinements in a high power neutral beam heated plasma are improved by a lower hybrid current drive (LHCD) in JT-60. A clear correlation between the improvement of the energy confinement time and the decrease of the plasma internal inductance caused by LHCD is observed. The energy confinement time of the profile-controlled plasma by LHCD is close to the ohmic confinement time and does not degrade with the beam absorption power up to 11 MW.

1. Introduction

Sawtooth stabilization by the lower hybrid current drive (LHCD) have been reported in many tokamaks (PLT\(^{(1)}\), ALCATOR-C\(^{(2)}\), PETULA\(^{(3)}\), ASDEX\(^{(4)}\)). Stabilization of sawtooth oscillations leads to the increase of central electron temperature and consequently may improve the energy confinement time. The peaked temperature profile obtained by sawtooth stabilization has a quite different profile from that of usual OH plasmas and additionally heated plasmas\(^{(1)}\). These results indicate that LHCD can decouple the electron temperature profile from the current profile and may lead us to control the MHD stability and the energy confinement property. Recent experiment in ASDEX shows that stabilization of sawteeth in the neutral beam (NB) heated plasma by LHCD has improved the energy confinement time by a factor of 1.3 as compared with the case in the presence of sawteeth\(^{(5)}\). This improvement arises from the increase of the central electron temperature due to the sawteeth stabilization.

In this paper improvements of the energy and the particle confinement in the high power NB heated plasma by LHCD are reported. Experiments were carried out mainly with relatively high-q discharges \((q_{\text{eff}} \sim 5.5)\) and only small volume where sawteeth dominate the energy loss exists within the plasma so that sawteeth does not largely affect on the total energy content. Even in these conditions, LHCD has largely improved the energy confinement and a clear correlation between the deformation of current profile from OH plasma and the improvement of energy confinement has been observed. The global energy confinement time of the profile-controlled plasma stays near the Ohmic confinement time and does not degrade with the absorption power up to 11 MW.

JT-60 is a large tokamak with a poloidal divertor having a major radius of \(R = 3.1\) m and a minor radius of \(a_p = 0.9\) m\(^{(6)}\). Experiments presented in this paper were performed in the hydrogen or the helium plasma with the parameter range \(n_e = 0.2 - 1.6 \times 10^{18}\) m\(^{-3}\), \(I_p = 0.5 - 1.5\) MA, \(B_T = 4\) T, \(q_{\text{eff}} = 3.7 - 11\). In the helium discharges the hydrogen was always employed as the prefilling gas so that the helium plasma contains the hydrogen minority. The torus input power of RF up to 1.4 MW was injected from the \(8 \times 4\) grill launcher at a frequency of 2 GHz. The power spectrum of the excited wave from this launcher peaks at the refractive index along the magnetic field \(N_p = 1.7\) with the width \(\Delta N_p \sim 1\) can be obtained by the toroidal phasing \(\Delta \phi = 90^\circ\). The hydrogen
having the port-through power up to 20 MW with the beam energy of 40 - 70 keV was almost perpendicularly injected to the LHCD plasma. Relatively high current drive efficiency $\eta_{CD} = \frac{n_e (10^{12} \text{m}^{-3}) R(m) I_{RF}(\text{MA})}{P_{LH}(\text{MW})} = 1.7$ for the Ohmic heated plasma and the improvement of drive efficiency by the combination with the NB heating ($\eta_{CD} = 2.0 - 3.0$) were successfully obtained in JT-60(7).

2. Improvement of the particle confinement time

In LHCD experiments on VERSATOR-II a significant density increase ($\Delta n_e / n_e = 0.5 - 2$) and the improvement of the global particle confinement time ($\tau_p (\text{LHCD}) \approx 2.3 \tau_p (\text{OH})$) have been observed (8). In NB heated plasma, the global particle confinement time was investigated in JT-60. Figure 1 shows time evolutions of the electron density $n_e$, $I_p$, power of NB and RP, the plasma current $I_p$ and the loop voltage $V_L$ for the combination of NB and LHCD (solid lines) and for the NB heating into the OH plasma (broken lines). The bottom box of this figure is density profiles at $t = 6$ sec. After the onset of LH pulse at $t = 3$ sec, the loop voltage $V_L$ becomes negative value and the plasma current $I_p = 0.7 \text{ MA}$ is completely replaced to the RF current. The slow decrease with the time constant of several seconds in $\beta_p + \delta_p/2$ during the LH pulse shows the broader current profile was realized by LHCD than by the OH discharge. Under these conditions, the significant density increase form $0.33 \times 10^{19} \text{ m}^{-3}$ to $1.15 \times 10^{19} \text{ m}^{-3}$ was observed during the additional NB pulse. On the other hand, the NB heating into the OH plasma shows a modest increase from $0.33 \times 10^{19} \text{ m}^{-3}$ to $0.55 \times 10^{19} \text{ m}^{-3}$. The density increase of the combined NB heating with LHCD was always larger than that of the other. A comparison between both density profiles at $t = 6$ sec as shown in the bottom box of this figure indicates that the more peaked density profile is formed for the combination of NB and LHCD. The sharp density profile may mean that the particle diffusion is suppressed in the core region of the plasma. The above results suggest that the particle confinement in the NB heated plasma can be improved by LHCD.

Figure 2 shows the density dependence of the global particle confinement time $\tau_p$ for OH plasmas (open notations) and NB heated (closed notations) where the particle confinement time is calculated.
NB(6) having the port-through power up to 20 MW with the beam energy of 40 - 70 keV was almost perpendicularly injected to the LHCD plasma. Relatively high current drive efficiency \( \eta_{CD} = \frac{n_e (10^{13} \text{m}^{-3}) R(m) I_{RF}(\text{MA})}{P_{LH}(\text{MW})} = 1 \sim 1.7 \) for the Ohmic heated plasma and the improvement of drive efficiency by the combination with the NB heating (\( \eta_{CD} = 2 - 3 \)) were successfully obtained in JT-60(7).

2. Improvement of the particle confinement time

In LHCD experiments on VERSATOR-II a significant density increase (\( \Delta n_e / n_e = 0.5 - 2 \)) and the improvement of the global particle confinement time (\( \tau_p \) (LHCD) \( \sim 2.3 \) \( \tau_p \) (OH)) have been observed(8). In NB heated plasma, the global particle confinement time was investigated in JT-60. Figure 1 shows time evolutions of the electron density \( n_e \), \( B_p^2 + z_i / 2 \), port-through powers of NB and RF, the plasma current \( I_p \), and the loop voltage \( V_p \) for the combination of NB and LHCD (solid lines) and for the NB heating into the OH plasma (broken lines). The bottom box of this figure is density profiles at \( t = 6 \) sec. After the onset of LH pulse at \( t \sim 3 \) sec, the loop voltage \( V_p \) becomes negative value and the plasma current \( I_p = 0.7 \) MA is completely replaced to the RF current. The slow decrease with the time constant of several seconds in \( B_p + z_i / 2 \) during the LH pulse shows the broader current profile was realized by LHCD than by the OH discharge. Under these conditions, the significant density increase from \( 3.3 \times 10^{13} \) \( \text{m}^{-3} \) to \( 1.15 \times 10^{13} \) \( \text{m}^{-3} \) was observed during the additional NB pulse. On the other hand, the NB heating into the OH plasma shows a modest increase from \( 3.3 \times 10^{13} \) \( \text{m}^{-3} \) to \( 0.55 \times 10^{13} \) \( \text{m}^{-3} \). The density increase of the combined NB heating with LHCD was always larger than that of the other. A comparison between both density profiles at \( t = 6 \) sec as shown in the bottom box of this figure indicates that the more peaked density profile is formed for the combination of NB and LHCD. The sharp density profile may mean that the particle diffusion is suppressed in the core region of the plasma. The above results suggest that the particle confinement in the NB heated plasma can be improved by LHCD.

Figure 2 shows the density dependence of the global particle confinement time \( \tau_p \) for OH plasmas (open notations) and NB heated (closed notations) where the particle confinement time is calculated.
by using the global particle balance equation with the H$_0$ radiation profile\(^{(9)}\). The particle confinement time in the NB heated plasma is shorter than that of the Ohmic plasma by a factor of about 2. The particle confinement time in the combination of NB heating and LHCD is plotted by an asterisk(*) this value is higher than that of the usual beam heating by a factor of about 1.3. We can say that the global particle confinement time in the NB heated plasma is improved by the LHCD.

3. Improvement of the energy confinement

The combined NB heating experiments with LHCD were carried out in relatively low density regime because the injected power of RF was not high enough to drive RF current in the high density plasma. Therefore the temperature measurement using the Thomson scattering was not available in these experiments and only the magnetic measurement to identify the incremental stored energy was employed here.

Figure 3 shows time evolutions of the loop voltage $V_L$, the Shafranov Lambda $\Lambda \equiv \beta_p + \ell_\perp/2 - 1$ and the line integrated electron density $n_e L$ for the NB heating into the OH plasma (a), and the combined NB and LH (b) and (c). In the case (a), the NB power with the beam energy of 40 keV was injected to the helium discharge having the average electron density of $0.2 \times 10^{19}$ m$^{-3}$. An increase of the stored energy $\Delta W_K$ is 0.21 MJ with the beam absorption power of 3.4 MW and then the incremental energy confinement time $\tau_{INC} \equiv \Delta W_K / P_{abs}$ of 62 msec is obtained. In the case (b), two RF pulses were applied to the almost the same condition with the case (a). As switched on at $t = 3$ sec with the pulse length $\Delta t_{RF} = 0.5$ sec, the first pulse is not seen in this figure. The second pulse was applied at $t = 4$ sec about 1 sec before the NB pulse. During the RF pulse the plasma current $I_p$ of 1 MA is replaced by the RF current as shown in the loop voltage. After a rapid increase of $\Lambda \equiv \beta_p + \ell_\perp/2 - 1$ at the initial stage of RF pulse, it decrease slowly with the time constant of several seconds. The change of $\Lambda$ in this period can be interpreted as being mainly due to the change of the plasma internal inductance $L_i$. While the rapid rise of $\Lambda$ contains the increase of the poloidal beta value $\beta_p$ due to the formation of the electron tail, this rise cannot be explained by the increase of $\beta_p$ alone. These changes
by using the global particle balance equation with the $H_0$ radiation profile\(^{(9)}\). The particle confinement time in the NB heated plasma is shorter than that of the Ohmic plasma by a factor of about 2. The particle confinement time in the combination of NB heating and LHCD is plotted by an asterisk\(^{(9)}\) this value is higher than that of the usual beam heating by a factor of about 1.3. We can say that the global particle confinement time in the NB heated plasma is improved by the LHCD.

3. Improvement of the energy confinement

The combined NB heating experiments with LHCD were carried out in relatively low density regime because the injected power of RF was not high enough to drive RF current in the high density plasma. Therefore the temperature measurement using the Thomson scattering was not available in these experiments and only the magnetic measurement to identify the incremental stored energy was employed here.

Figure 3 shows time evolutions of the loop voltage $V_L$, the Shafranov lambda $\Lambda = \beta_p + l_i/2 - 1$ and the line integrated electron density $n_e L$ for the NB heating into the OH plasma (a), and the combined NB and LH (b) and (c). In the case (a), the NB power with the beam energy of 40 keV was injected to the helium discharge having the average electron density of $0.2 \times 10^{19}$ m\(^{-3}\). An increase of the stored energy $\Delta W$ is 0.21 MJ with the beam absorption power of 3.4 MW and then the incremental energy confinement time $t_{E}^{INC}$ of 62 msec is obtained. In the case (b), two RF pulses were applied to the almost the same condition with the case (a). As switched on at $t = 3$ sec with the pulse length $\Delta t_{RF} = 0.5$ sec, the first pulse is not seen in this figure. The second pulse was applied at $t = 4$ sec about 1 sec before the NB pulse. During the RF pulse the plasma current $I_p$ of 1 MA is replaced by the RF current as shown in the loop voltage. After a rapid increase of $\Lambda = \beta_p + l_i/2 - 1$ at the initial stage of RF pulse, it decrease slowly with the time constant of several seconds. The change of $\Lambda$ in this period can be interpreted as being mainly due to the change of the plasma internal inductance $L_i$. While the rapid rise of $\Lambda$ contains the increase of the poloidal beta value $\beta_p$ due to the formation of the electron tail, this rise cannot be explained by the increase of $\beta_p$ alone. These changes
in the internal inductance $\mathcal{L}_i$ during LHCD are explained in the appendix by using the equation of the magnetic field diffusion. We can infer that the broad current profile as compared with the case (a) are realized before the injection of NB. Under these conditions the effective absorption power $P_{abs} = \dot{\mathcal{W}}$ of 4.6 MW leads to the increase of the stored energy of 0.4 MJ and the corresponding incremental energy confinement time is around 87 msec. Clear improvement on the incremental energy confinement time is observed in the combination of NB heating and LHCD. The case of a high power NB heating of the LHCD plasma is shown in the figure of (c). In order to avoid a large shine through of the NB the electron density is increased by the short gas puffing before the NB pulse. The increase of stored energy $\Delta \mathcal{W}_e = 0.96$ MJ with the effective absorption power of 10.7 MW and the incremental confinement time $\tau_E^{INC} = 90$ msec are obtained. The energy confinement is improved by LHCD even in the high power NB heating. It is important to note the fact that $\tau_E^{INC}$ for the case (c) where the strong gas puffing before the NB pulse was employed is almost the same value for the case (b). This implies that the time constant of the change of current profile in the core plasma where the global energy confinement is determined is so long that the short gas pulse does not affect the current profile. This fact is supported by MHD activities as mentioned later. We can say that the change of the internal inductance $\mathcal{L}_i$ during the NB pulse is relatively small for a large change of $\Delta \mathcal{L} = \mathcal{L}_p \frac{\partial \mathcal{L}}{\partial \mathcal{L}} / 2 - 1$ as shown in Fig. 3(c).

The global energy confinement time $\tau_E$ is determined as

$$\tau_E = \frac{\dot{W}_{OH} + \dot{W}_{LH} + \Delta \mathcal{W}_e}{P_{OH} + P_{LH}^{abs} + P_{abs}}$$

where $\dot{W}_{OH}$, $\dot{W}_{LH}$, $\Delta \mathcal{W}_e$ are the Ohmic stored energy, the increases of stored energy by RF power and the NB power, and $P_{OH}$, $P_{LH}^{abs}$, $P_{abs}$ are the Ohmic input power, absorption powers of LH and NB. We cannot identify $\dot{W}_{OH}$, $\Delta \mathcal{W}_LH$ and $P_{LH}^{abs}$ accurately from the magnetic measurement. In order to estimate roughly the global energy confinement time, we neglect $\Delta \mathcal{W}_LH$ and $P_{LH}^{abs}$ in eq. (1) and determine $\dot{W}_{OH}$ from the scaling law for the OH plasma in JT-60; $\dot{W}_{OH}(MJ) = 0.157 \frac{I_p(\text{MA})^{0.75} n_e(10^{13} \text{m}^{-3})^{0.2}}{\text{p}} (11)$. These assumptions are valid when the beam power is high enough to set $P_{abs} > P_{LH}$, $P_{OH}$ and $\dot{W}_e << \Delta \mathcal{W}_LH$, $\dot{W}_{OH}$ as this experiment. Figure 4 shows the density
dependence of $\tau_E$ for the absorption power of NB is 11 MW and $I_p = 1.0$ MA. The energy confinement time of the normal NB heating and the combined NB heating with LHCD are plotted as open and closed circles, respectively. The Ohmic confinement time for $n_e < 2 \times 10^{14}$ m$^{-3}$, $I_p = 1.0$ MA stays between two solid lines. Broken line is the $\tau_E$ calculated by the Kaye-Goldston scaling\(^{(12)}\). We can see that the global energy confinement time for the combined NB heating with LHCD is rather near the Ohmic confinement time. Global energy confinement times for the case of Fig. 3(a), (b) and (c) are estimated roughly to $\tau_E \approx 69$ msec, 100 msec and 107 msec, respectively. Thus the global confinement time $\tau_E$ in the combined heating does not degrade with the absorption power up to 11 MW which is almost the maximum absorption power of JT-60 NB heating in this density regime.

Figure 5 shows the dependence of the increase of stored energy $\Delta W^*$ on the effective absorption power $P_{abs} - \dot{W}$ for the NB heating into the OH plasma (open symbols) and for the combined NB heating with LHCD (closed symbols). The maximum incremental energy confinement time for the NB heating alone is around 70 msec while 90 msec for the combined heating. It is interesting that the improvement of the confinement time is not always realized by the combination of NB and LHCD. The confinement time $\tau^\text{INC}_E$ for the LH + NB shot without the improvement stays in the usual NB heating level. We found that the change of the current profile due to LHCD is the key parameter to improve the energy confinement. This fact is shown in Fig. 6(a) where the horizontal axis is the change of the $\Delta \equiv \beta_p + \beta_1/2 - 1$ due to LHCD during the time interval from the applications of RF pulse to the beam injection, that is,

$$\Delta \equiv \Delta(\beta_p + \beta_1/2 - 1)$$

$$= \Delta(\text{just before NB pulse}) - \Delta(\text{just before LH pulse}) \quad (2)$$

and the vertical axis is $\tau^\text{INC}_E$. The increase of $\beta_p$ due to the formation of the electron tail can be estimated roughly by assuming that the monochromatic electron beam having the energy corresponding to $N_p = 1.7$ carry the total RF current. Since $\Delta \beta_p \approx 0.01$ is deduced for $I_p = I_{RF} = 1$ MA from this estimation, we can put approximately $\Delta \beta_p \approx \Delta \beta_{p1}/2$. As shown in this figure the improvement of the energy confinement is attained when the broader current profile is realized by LHCD than by
the OH discharge. The incremental energy confinement times in the combined heating are plotted as a function of $\beta_p + \frac{\beta}{4}$ just before the NB pulse in Fig. 6(b) for the case of $I_p = 1$ MA. Since the poloidal beta $\beta_p$ is small before the NB onset ($\beta_p \ll \beta/4$), the horizontal axis can be regarded approximately as $\frac{\beta}{4}$. Apparently broad current profile obtained by LHCD leads to the improvement of energy confinement. In the NB heating into the OH plasma, the energy confinement time did not depend strongly on the safety factor $q_{eff}$ and the NB heating in the ramp up phase of the plasma current did not tend to improve the confinement time (13). Therefore we can say that the broad current profile obtained by LHCD do improve the confinement time.

According to the change of the current profile by LHCD, MHD activities are changed in the beam heated plasma. Since discharges discussed in this paper are relatively high $q$ discharge ($q_{eff} \approx 5.5$ for $I_p = 1$ MA, $B_T = 4$ T) and low density, large sawteeth were not observed in the NB heating into the OH plasma. Therefore the stabilization of sawteeth does not increase largely the total energy content. Figure 7 shows comparison of MHD activities inside the plasma of the usual NB heating (a), (b) and the combined heating (c), (d). The left hand side of this figure indicates time evolutions of the soft X-ray signals $S_x$ from the near center of plasma and the right side is radial profiles of the fluctuation level of soft X-ray $\Delta S_x / S_x$. In the usual NB heating as shown in Fig. 7(a), (b), strong MHD oscillations localized sharply near the plasma center have been observed at about the end of NB pulse. Fluctuation level reaches about 40 %. This oscillation is thought to be mainly the $m=1$ oscillation with a frequency of a few kHz and the safety factor at the magnetic axis supposed to be below unity. These MHD oscillations near the plasma center are dramatically suppressed in the combined NB heating with LHCD as shown in Fig. 7(c)(d). MHD oscillations having $\Delta S_x / S_x \approx 0.1$ have been found near the half radius. These results imply that the current profile is rearranged by LHCD so that the central $q$-value increases and the sharp on the current profile shifts to the outer region of plasma. This deduction is supported by the change of $\beta_p + \frac{\beta}{4}/2 - 1$ during the LH pulse. A candidate of the possible explanations of the improvement of the energy confinement by LHCD is the stabilization effect of these strong MHD oscillations in the center of the plasma. We can also deduce that the stabilization of these fluctuations may result from the rearrangement of current profile.
and the improvement of energy confinement may derive from the other mechanism.

Finally Fig. 8 shows the relation between $\Delta \eta_{\text{LH}}$ defined as eq. (2) and the RF power normalized by the electron density and the plasma current $P_{\text{LH}}/n_e I_p^0$. The horizontal axis is proportional to $I_{\text{RF}}/I_p$. As shown in this figure, active control of the current profile by the input RF power and the electron density are possible. In other words we can externally control the energy confinement time in the NB heated plasma. Other parameter dependences of $\Delta \eta_{\text{LH}}$ such as the electron temperature and the launcher phasing and so on have been not studied for the restriction of the machine time in this series of experiments yet.

4. Conclusions and Discussions

We conclude in our experimental results as following way,

(1) LHCD has improved the global particle confinement time in the NB heated plasma by a factor of around 1.3.

(2) The energy confinement time in the NB heated plasma has been improved by LHCD and apparent correlation between the improvement of confinement and the change of the internal inductance caused by LHCD has been observed. In the profile-controlled plasma by LHCD the incremental energy confinement time $\tau_E^{\text{INC}}$ has been improved by a factor of 1.3-1.8 as compared with that of NB heating alone.

(3) The global energy confinement time $\tau_E$ of well-controlled plasma by LHCD has been close to the Ohmic level and did not degrade with the absorption power up to 11 MW.

Combined NB heating to the profile-controlled plasma by LHCD seems a possible method to realize the break-even condition in JT-60. For this goal we need to control the current profile in a higher plasma current $I_p \geq 2$ MA and in a higher electron density $n_e \geq 2 \times 10^{19} \text{ m}^{-3}$. These experiments were not studied in this series of experiment because there was not enough time for the launcher aging. In JT-60, individually controllable 3 units of LH system have a total generator power of 24 MW, and a next torus power of around 15 MW with a pulse duration of 10 sec at frequency from 1.7 GHz to 2.3 GHz. Therefore we can examine the way to approach the break-even condition by the combination of profile control of LHCD and the high power NB heating. After the broad current
and the improvement of energy confinement may derive from the other mechanism.

Finally Fig. 8 shows the relation between $\Delta\lambda_{\text{LH}}$ defined as eq.(2) and the RF power normalized by the electron density and the plasma current $I_{\text{RF}}/I_{\text{e_p}}$. The horizontal axis is proportional to $I_{\text{RF}}/I_{\text{p}}$. As shown in this figure, active control of the current profile by the input RF power and the electron density are possible. In other words we can externally control the energy confinement time in the NB heated plasma. Other parameter dependences of $\Delta\lambda_{\text{LH}}$ such as the electron temperature and the launcher phasing and so on have been not studied for the restriction of the machine time in this series of experiments yet.

4. Conclusions and Discussions

We conclude in our experimental results as following way,

(1) LHCD has improved the global particle confinement time in the NB heated plasma by a factor of around 1.3.

(2) The energy confinement time in the NB heated plasma has been improved by LHCD and apparent correlation between the improvement of confinement and the change of the internal inductance caused by LHCD has been observed. In the profile-controlled plasma by LHCD the incremental energy confinement time $\tau_{E}^{\text{INC}}$ has been improved by a factor of 1.3-1.8 as compared with that of NB heating alone.

(3) The global energy confinement time $\tau_{E}$ of well-controlled plasma by LHCD has been close to the Ohmic level and did not degrade with the absorption power up to 11 MW.

Combined NB heating to the profile-controlled plasma by LHCD seems a possible method to realize the break-even condition in JT-60. For this goal we need to control the current profile in a higher plasma current $I_{\text{p}} \geq 2$ MA and in a higher electron density $n_{\text{e}} \times 2 \times 10^{19}$ m$^{-3}$. These experiments were not studied in this series of experiment because there was not enough time for the launcher aging. IN JT-60, individually controllable 3 units of LH system have a total generator power of 24 MW, and a next torus power of around 15 MW with a pulse duration of 10 sec at frequency from 1.7 GHz to 2.3 GHz. Therefore we can examine the way to approach the break-even condition by the combination of profile control of LHCD and the high power NB heating. After the broad current
profile is realized by LHCD at the density lower than the density limit of LHCD (this limit of 2 GHz may be around $3 \times 10^{19} \text{ m}^{-3}$ for the hydrogen and $\geq 4 \times 10^{19} \text{ m}^{-3}$ for the helium), we can approach to the goal by the combination of the short gas puffing and the NB heating as employed in Fig. 3(c).

Fig. 1 Time evolutions of the electron density $\bar{n}_e$, $\beta_p + \frac{\theta_I}{2}$, the loop voltage $V$, and the density profile at $t = 6$ sec for the combined NB heating with LHCD (solid lines) and for the usual NB heating (broken lines). $B_T = 4$ T, $I_p = 0.7$ MA, $n_e$ discharge and the beam energy $V_{acc} = 40$ keV.
Fig. 2 Density dependence of the global particle confinement time $\tau_p$ for the Ohmic plasmas (open symbols) and the usual NB heated plasma (closed symbols). An asterisk(*) indicates the shot of the combined NB heating with LHCD ($I_p = 1$ MA, $B_T = 4$ T, He discharge, $P_{LH} = 1.1$ MW).
Fig. 3 The improvement of the energy confinement time. (a) shows the usual NB heating with $V_{\text{acc}} = 40$ keV, $P_{\text{abs}} = 3.4$ MW, $\Delta W = 0.207$ MJ, $\tau_{E, \text{INC}} = 61$ msec, (b) is the combined heating with $V_{\text{acc}} = 40$ keV, $P_{\text{abs}} = 4.4$ MW, $P_{\text{LH}} = 1.1$ MW, $\Delta W = 0.315$ MJ, $\tau_{E, \text{INC}} = 71$ msec. (c) shows the high power combined heating with $V_{\text{acc}} = 70$ keV, $P_{\text{abs}} = 10.7$ MW, $P_{\text{LH}} = 1.1$ MW, $\Delta W = 0.96$ MJ, $\tau_{E, \text{INC}} = 90$ msec. $B_T = 4$ T, $I_p = 1$ MA, $B_e$ plasma and $\lambda \equiv b_p + \lambda_p/2 - 1$. 
Fig. 4 Density dependence of the global energy confinement time $\tau_E$ for the combined NB heating with LHCD (●) and for the NB heating alone (○). The Ohmic confinement time for $n_e < 2 \times 10^{19}$ m$^{-3}$, $I_p = 1$ MA stays inside two solid lines and the broken line is the $\tau_E$ calculated by the Kaye-Goldstone scaling law. $I_p = 1$ MA, $B_T = 4$ T.

Fig. 5 The increase of the stored energy $\Delta W^*$ against $P_{\text{abs}} - W$. Open symbols (○,△) show the data of the usual NB heating and closed symbols (●,▲) is the combined NB heating with LHCD.
Fig. 6 (a) is the dependence of the incremental energy confinement time $\tau_{E^{\text{INC}}}$ on the change of $\lambda = \beta_p + \ell_1/2 - 1$ due to LHCD $\Delta A_{\text{LH}}$ defined in eq. (2) and (b) is the $\tau_{E^{\text{INC}}}$ against $\beta_p + \ell_1/2$ just before the NB injection for $I_p = 1$ MA.
Fig. 7 Comparisons of the MHD activity of the usual NB heating (upper traces) and of the combined heating (lower traces). The left hand side of this figure shows time evolutions of the soft x-ray emission $S_x$ from the near center chords and the right side is radial profiles of the fluctuation $\Delta S_x / S_x$. $I_p = 1$ MA, $B_T = 4$ T, $n_e = 0.7 \times 10^{19}$ m$^{-3}$ and $1.4 \times 10^{19}$ m$^{-3}$ for LH + NB and NB alone, respectively.
Fig. 8. Dependence of $\Delta A_{\text{LH}}$ defined in eq. (2) on $P_{\text{LH}}/\bar{n}_e I_p$. 
Appendix  Current Profile during LHCD

It is interesting to investigate the transition of current profile during LHCD. For this purpose, we have done the simplified simulation and compare it with the experimental results.

(i) Current Profile Model

We use the cylindrical coordinate, so that the diffusion equation of the poloidal magnetic field \( B_p \), which can be derived from Maxwell's equation and Ohm's low, is:

\[
\frac{3B_p}{\partial t} = \frac{2}{\partial r} \left( \frac{n}{\nu_0} \frac{1}{r} \frac{2}{\partial r} r B_p - \frac{n}{\partial r} \eta_{CD} \right)
\]

\( \eta \): Spitzer Resistivity

\( j_{CD} \): noninductive current produced by LHCD

Boundary condition of eq.(1) is:

\[
B_p (0) = 0, \quad B_p (a) = \frac{\nu_0 I_p}{2 a}
\]

\( I_p \): total plasma current, which is kept constant

\( a \): plasma minor radius

Then plasma current density \( j \) can be obtained from eq.(1).

\[
\frac{1}{r} \frac{3}{\partial r} (r B_p) = \nu_0 j
\]

The resistivity of the noninductive current is assumed to be zero so that the electric field is:

\[
E = \eta (j - j_{CD})
\]

From the result of eq.(1), plasma internal inductance \( L_I \) and one turn voltage \( V_h \) can be calculated as follows.

\[
L_I = \frac{8 \pi \int_0^a \frac{B_p^2}{2 \mu_0} 2\pi r \, dr}{\nu_0 \frac{I_p^2}{2}}
\]

\[
V_h = \frac{8 \pi \int_0^a \frac{B_p^2}{2 \mu_0} 2\pi r \, dr}{\nu_0 \frac{I_p^2}{2}}
\]
\[ V_L = v_0 \frac{R}{4} \frac{I_p}{I_p} + \frac{2\pi}{T_p} + j^2 2\pi rdr \] (6)

Therefore we can look for the reasonable profile of noninductive current \( j_{CD} \) in order to reproduce the transition of \( \xi_1 \) and \( V_L \), which are measured in the experiment.

During LHCD, profile of electron temperature is assumed to be fixed and total plasma current is controlled to be constant without time delay. Noninductive current driven by LHRF is assumed to flow from the beginning of LHCD total of which is 100% of plasma current.

(ii) Comparison of \( V_L \) and \( \beta_p + \frac{\xi_1}{2} \)

The typical experimental result of LHCD is shown in Fig. A1(A).

In this case power of LHRF is about 1 MW. After about 200 ms from the start of LHCD, \( \Lambda = \beta_p + \frac{\xi_1}{2} - 1 \) rises to its maximum value (\( \Delta \Lambda \approx 0.05 \)) and one turn voltage \( V_L \) drops to zero. Then \( \Lambda \) decreases slowly at the rate of 0.07/sec. The increase of \( \beta_p \) caused by the formation of electron tail is small (\( \Delta \beta_p \approx 0.01 \)) as discussed in the section 3, so that the transition of \( \Lambda \) is due to the change of \( \xi_1 \).

In order to reproduce these transition of \( \xi_1 \) and \( V_L \), we have sought for a profile of noninductive current, using the reasonable temperature profile presented in eq.(7).

\[ T_e(r) = (T_0 - T_{\text{edge}})(1 - (r/a)^2)^4 + T_{\text{edge}} \] (7)

Finally we have obtained eq.(8) as the noninductive current profile.

\[ j_{CD}(r) = \begin{cases} j_0(1 - (r/r_B)^2) & r \leq r_B \\ 0 & r_B \leq r \leq a \end{cases} \] (8)

Transition of \( V_L \) and \( \xi_1 \) can be explained qualitatively, using the result of simulation as follows. Fig. A2 shows the change of plasma current profile. Before the start of LHCD, the current has peaked profile because of high \( q(a) \) (\( \approx 5.2 \)). When LHCD starts, return current of noninductive current flows in the opposite direction to keep the
magnetic flux. Therefore the negative voltage, caused by this return current is build up and propagates to the plasma surface and center. Resistivity of the plasma surface region is very high, so that this negative voltage propagates more quickly to the plasma surface than to the center. At this time plasma current in the surface region disappears as shown in Fig. A2, so that $I_i$ rises a little. After that $I_i$ decreases slowly. Because current in the central region decreases with long time constant for the sake of low resistivity.

(iii) Discussion

It is found that the transition of $\omega$ and $V_\perp$ during LHCD can be explained by very simple model. However, in order to get more physical and quantitative discussion, we have to do more reasonable treatment of the current profile and resistivity under the condition of driving the noninductive current by LHRF.
Fig. A1 $l_1$ and $V_L$

(A) Experiment. (B) Simulation: $V_L$ and $l_1$ show almost the same behavior with (A). $l_1$ decreases at the rate of $-0.14$/sec ($\Lambda = -0.07$/sec). In this simulation parameters are set as follows.

$r_B = 0.6$ m, $T_O = 3$ keV, $T_{\text{edge}} = 200$ eV.
Fig. A2 Transition of Current Profile
Current profile in the case of Fig. A1(B) is presented. \( A \) is the beginning of the LHCD, after which current profile changes....
\( \oplus \) 0.1 sec \( \ominus \) 1 sec \( \otimes \) 2 sec. \( \infty \) is the profile of the noninductive current \( j_{CD}(r) \).
